## **Digital Microphone**

### **Field of the invention**

This Invention relates to a digital microphone and an integrated circuit comprising an amplifier with a feedback filter and an analogue-to-digital  
5 converter.

### **Background of the invention**

The concept of digital microphones are not new, in fact it is a very obvious idea to combine a microphone preamplifier with an A/D converter. But finding  
10 a solution of how to implement a microphone preamplifier and an A/D converter on a single chip with very high performance which can be mass produced at very low cost is not a trivial task. Generally, and also in this specific context, high performance is characterized by low noise, low distortion, large dynamic range and other well known properties.

15 Expediently, for implementation in consumer/telecommunications products a microphone with such properties should be implemented in a single ASIC (Application Specific Integrated Circuit) with few or no external components and with a minimum die area. Thus achieving low cost, high performance and  
20 enabling miniature digital microphones.

### **Summary of the invention**

In the following, firstly, some observations in relation to the present invention is outlined, secondly, objects of the invention are summarised, and thirdly  
25 aspects of the invention are summarised.

In recent years so-called sigma delta modulators have become very popular for implementing A/D converters. They exhibit many virtues, which among others are: no need for high precision components; high linearity; and for so-called single loop modulators also the advantages of small die area, low  
30 voltage operation and possibly very low power consumption. These are

advantages which makes sigma delta modulators very suitable for single chip implementations.

5 A special class of sigma delta modulators are 1-bit quantized sigma delta modulators. This type of modulators are especially suited for low cost implementations as the complexity of the analogue part of the A/D converter is minimal compared to other types of A/D converters. A complete 1-bit sigma delta converter consists of a 1-bit analogue sigma delta modulator and a digital decimation filter only. Even the normally required anti aliasing filter can  
10 be omitted and replaced by a simple RC-filter. This is due to the fact that heavy over-sampling is used and thus the digital decimation filter performs the job of anti-aliasing filtering.

15 1-bit sigma delta modulators are very simple to implement in the analogue domain. Thus they are very suitable for low cost miniature digital microphones. Unfortunately they do also have disadvantages. Especially 1 bit sigma delta modulators exhibit the so called idle mode tones, which are low level tones in the audio band caused by low frequency or DC levels at the input of the modulator. This is the reason why 1-bit sigma delta modulators  
20 has been abandoned by many despite of its many virtues. One can use dither to remove this problem or design chaotic modulators: but all of these solutions has the effect that the complexity of the design increases dramatically. Thus both power consumption and die area increases dramatically.

25 This 'idle mode tones' effect has caused sigma delta modulators less suitable for high quality audio applications. Apparently, this may seem to be of little concern in consumer/telecom applications. But as the demand for low cost digital microphones increases higher demands of performance, which may  
30 almost equal the performance of high quality audio, will follow. Consequently,

the 'idle mode tones' effect will become an increasing problem also for telecom applications.

5 In order to achieve high performance from the digital microphone, the preamplifier of the digital microphone ASIC has to have as high performance as possible ie low noise, low distortion, high dynamic range etc. According to presently available technology, CMOS technology is a prerequisite to achieve low noise performance and it can be shown that the input stage of the amplifier can be optimized in respect to noise. That is, there exist an area of  
10 the input device(s) for which the input related noise is minimum. Also the input impedance should be as large as possible in order to minimize the noise. This is especially dominant for new and thinner types of telecom microphones which has a much lower sensitivity and cartridge capacitance than previously experienced.

15 Unfortunately this has the consequence that the preamplifier becomes able of amplifying low frequency signals arising from the sound pressure of a door slamming, car rumbling or just changes in sensitivity of the microphone element due to humidity changes. This adds to the above explained problem  
20 of idle tone modes if a 1-bit sigma delta modulator is used. In fact also 2-bit and modulators with even more levels will exhibit such behaviour when exposed to such low frequency signals.

25 Additionally, these low frequency signals reduces the dynamic range and creates inter-modulation distortion as the low frequency signals can be excessive in amplitude.

30 The problem is worsened as the telecom microphones are becoming smaller and thinner and thus more gain is required from the preamplifier. However, normally the disturbing low frequency signals do not become smaller in amplitude. Thus the relative effect of the disturbance will increase.

5 So there is a need for a configuration of a preamplifier and an A/D converter which is suited for thin ECM cartridges with a very low cartridge sensitivity and capacitance. Additionally, the configuration should provide a very high performance on noise, dynamic range and distortion. Moreover, it shall be feasible to implement the configuration on a single die with a very small area in combination with few or none external components.

10 Today the architecture of the mobile phone consists of a two or more separate, integrated circuit chips. Typically, these chips comprise a Digital Signal Processor, DSP, a Radio Frequency, RF, chip and a baseband chip. The baseband chip integrates most low frequency analogue functions. But when the transducers becomes digital and integrates the analogue functionality in the transducer, the baseband chip becomes redundant and a completely new mobile architecture with all analogue functionality build into the transducers will arise. This also means that a regulated, low noise power supply for the analogue circuitry will not be provided in the same way in the future mobile phone architecture. This means that the digital transducer/microphone will have to have this power supply build in.

20 So there is a need for a digital microphone chip with build in power supply regulator. At the same time this should be implemented with the lowest possible die area and the fewest possible numbers of external components.

25 The vast majority of microphones for telecom applications has a microphone membrane that is charged with a static electrical charge during manufacturing. If this charge disappears the performance of the microphone is completely or almost completely destroyed. Therefore, these microphones cannot be assembled using reflow soldering since the high temperatures during this process will destroy the permanent charge in the electret and thus deteriorate the performance of the microphone.

30

Solutions to this problem has been shown, in the form of eg Silicon microphones, so that reflow soldering can be used and thus lower the cost of the assembly process. This solution has the advantage of offering easy  
5 assembly of microphones having many more terminals than today's microphones. This is a major advantage in the case of a digital microphone. These solutions require an on-chip voltage pump for biasing the microphone and thus there is a need for a digital chip with added voltage pump and a preamplifier optimized for a silicon microphone. All of this with very low cost  
10 added.

To conclude, the topology of the integrated circuit in a digital microphone plays a major role in how the complete digital microphone performs. That is, an optimal topology of the IC will give the best performance vs. cost ratio.  
15

Turning now to different objects of the invention:

It is an objective of the present invention to provide a combination of a preamplifier and a A/D converter with the lowest possible noise, largest  
20 dynamic range, low distortion and at the same time having the smallest possible die area.

It is an objective of the present invention to provide a digital amplifier ASIC which is able to handle slowly varying signals with a relatively large amplitude  
25 at its input terminal while at the same time being able to amplify a low level signal with a higher frequency without distortion and without creating in-band idle mode tones.

It is an objective of the present invention to provide a digital amplifier ASIC which performance is very insensitive towards leakage and parasitic  
30 capacitances connected to the input.

It is an objective of the present invention to provide a single chip solution with all functions integrated. That is a preamplifier, A/D converter, power supply regulator digital processing circuitry etc. All integrated on the same chip with  
5 smallest possible die area and few or no external components.

Turning now to different aspects of the invention:

The invention is provided in a **first aspect** by a digital microphone integrated  
10 circuit comprising a high-impedant biasing of an amplifier input, an amplifier with a low pass filter feedback, an anti-aliasing filter, and a sigma delta modulator. In accordance with the present invention an expedient architecture of a digital microphone integrated circuit has a preamplifier with a high pass filter function, followed by a low pass filter, followed by a sigma  
15 delta modulator or an A/D converter. In accordance with the present invention another expedient architecture has a preamplifier with a band-pass filter followed by a sigma delta modulator or an A/D converter.

This expedient architecture is based on the following signal processing  
20 blocks, which are at minimum required in the digital microphone IC: a low pass filter function to filter out the low frequency signals normally present at the input of the preamplifier; a preamplifier to buffer the high impedant microphone element and to amplify the signal in order to obtain a good signal to noise ratio for the overall system; an anti-aliasing filter to filter out the high  
25 frequency signal before they are sampled by the A/D converter, which can be implemented as a sigma delta converter.

As cost is a major concern in telecom microphones the topology should have the lowest possible cost for a given performance or the best given  
30 performance for a given cost. For analogue signal processing current consumption, signal to noise ratio, area and signal swings are dependent and

highly correlated parameters. That is, on the one hand, in order to get a high signal to noise ratio, large area and current are needed. On the other hand, however, if the signal wing is large the area savings and or current savings can be obtained. These observations can be used to optimize the system/topology for optimum performance or lowest cost.

5

Each of the above mentioned blocks can be analysed. First we will look at the two analogue filters i.e. the high pass filter and the low pass filter. The simplest forms of these consists of one resistor and one capacitor. Here the interesting parameters are area and noise. I.e. how should the capacitance and resistor values be chosen for a given signal to noise ratio in order to obtain the smallest possible area? For the high pass filter the noise from the resistor is low pass filtered by the coupling capacitance which means if the cut-off of the high pass filter is located at a low frequency e.g. Below the cut-off of the A-weighting function then the noise of the high pass filter can be minimized. As one normally is interested in having the cut-off of the high pass filter below the cut off of the A-weighting e.g. 100-200Hz, the size of the high pass filter can be made relatively small. The low pass filter (anti-aliasing filter) is different here since the noise can be minimized by moving the cut-off to a high frequency. The function of the low pass filter is that of an anti-aliasing filter and thus it should be have a cut-off frequency as low as possible. This is in contrast of what is needed to optimize for lowest area for a given signal to noise ratio. So it can be concluded that the low pass filter is more critical regarding noise and area than the high pass filter.

25

In order to optimize the signal to noise ratio in a chain of signal processing blocks the block closest to the source should have the largest gain. I.e. the preamplifier should have a large gain.

30

We can now describe how the optimal architecture when optimizing for signal to noise ratio and or area will look like. In order to obtain the best signal to

noise ratio for a capacitive microphone the input bias device of the preamplifier should have an impedance as large as possible. Thus pushing the noise from the input bias device to a frequency so low that the A-weighting weighs it out.

5

This will give the lowest possible noise but also very low settling of the input signal after power on of the system. Also slowly varying signals appearing from change in cartridge sensitivity due to humidity changes etc. will not be attenuated due to the low frequency cut-off of the biasing device.

10

The preamplifier must be connected directly to the microphone cartridge. And have a large gain in order to optimize overall noise performance. In order not to overload the preamp and to avoid that low frequency signal reaches the input of the modulator where it can cause the modulator to create idle mode tones. From this perspective the high pass filter should be placed as close to the preamp as possible. But obviously it is not possible to put it at the input as it would load the cartridge and putting it after the amplifier will not assure that the preamp doesn't get overloaded. The solution is to integrate the filter with the preamp ie to make a preamp with a high pass filter function and gain.

20

The low pass filter can now be put directly after the preamplifier as it should remove any high frequency signal before the signal is sampled ie preventing high frequency signals entering the sigma delta modulator. Because of the high gain of the preamplifier the noise of the low pass filter is now much less important and thus the area of this filter can be greatly reduced. To further reduce the chip area needed to implement an anti-aliasing filter function, the preamplifier incorporates a band-pass filter-function. Thereby, the sigma delta modulator can be coupled to receive an output signal from the preamplifier without additional intermediate filters. Thereby, an individual anti-aliasing filter is avoided.

25

30

So to conclude, a preferred microphone circuit architecture has a preamplifier with a high pass filter function, followed by a low pass filter, followed by a sigma delta modulator or an A/D converter.

5

This architecture is the optimum in respect of achieving the best performance and at the same time smallest die area. The optimum architecture is independent on how the different blocks are implemented. I.e. The preamplifier can be implemented as differential as well as single ended. Any of the blocks can be made single ended or differential. Or any combination hereoff. Or extra signal processing blocks such as filters buffers or amplifiers can be added. The arguments for the optimal architecture will still hold.

10

The invention is provided in **second aspect** by using a preamplifier having a lower gain at low frequencies compared to audio frequencies.

15

In order not to overload the preamplifier with low frequency signals then the gain at low frequencies should be low. This also goes for a differential implementation. But in this case the it is the single ended gain which should be lower at low frequencies than at audio frequencies.

20

The invention is provided in a **third aspect** by using a differential preamplifier converting the input signal into a common mode signal for low frequencies and into a differential signal for audio frequencies. Alternatively, a differential preamplifier converting the input signal into a common mode signal for lower frequencies and having a low-pass filter function for higher frequencies.

25

In a preferred embodiment, the differential preamplifier is configured as an instrumentation type amplifier with two inputs and a first and a second output, wherein the first and second input is arranged to receive a microphone signal, but wherein the inputs are coupled to receive the microphone signals substantially in phase at relatively low frequencies and substantially out of

30

phase at relatively high frequencies. Preferably, the relative high frequencies comprises the audible frequency range and higher frequencies.

5 The second input can be coupled to receive the microphone signal from the first input through a phase shifter, which has a substantial constant phase shift in the audible range and has a gradually shifting phase for gradually lower frequencies until a phase shift of about  $180 \pm 5$ , 10, 15, or 20 degrees relative to the phase shift in the audible range is realised. At that frequency the phase shift remains substantial constant for lower frequencies. The  
10 phase shifter can be of any order eg 1<sup>st</sup> order, 2<sup>nd</sup> order, 3<sup>rd</sup> order, 4<sup>th</sup> order or any higher order. However, a 1<sup>st</sup> order is preferred with regard to realise low chip die and low cost.

15 Alternatively, the second input can be coupled to receive the microphone signal from the first output through the phase shifter.

20 Preferably, the phase shift and the filter function is realised in an instrumentation amplifier by means of a RC circuit comprising a first and a second feedback path, each path coupled between the output and input of a respective amplifier in the instrumentation amplifier, and each path comprising a parallel coupling of a resistor and a capacitor, and both paths being coupled together at the amplifier input side of the paths by means of a capacitor.

25 The differential preamplifier is configured to provide frequencies below an audio band as common mode signals and audio band signals as differential mode signals. A circuit coupled to receive the differential signal will be able to suppress common mode signals and thus low frequency signals far better than if ordinary high pass filtering was used. Despite the increased  
30 complexity of using differential mode circuits as compared to single ended circuits the ability of suppressing low frequent signals has proved to be very

effective – also from a cost versus performance perspective. The frequency dependent phase shift required to achieve the common mode operation at low frequencies and the differential mode operation at higher frequencies can be obtained in various ways. Three types of achieving this phase shift are:

- 5       • A phase shifter coupled between inputs of the differential amplifier;
- A phase shifter cross coupled between an output of one side of the differential amplifier and an input of the opposite side of the differential amplifier;
- A combination of the above two types;
- 10       • A phase shifter cross coupled between a signal node at which a signal substantially in phase with the input signal to the preamplifier is present and an input of the opposite side of the differential amplifier

The invention is provide in a fourth aspect by using a simple 1st order RC filter as an anti-aliasing filter in combination with a high over sampling factor. Alternatively, the preamplifier is configured to implement the anti-aliasing filter by means of a feedback circuit.

In order to obtain the best signal to noise and at the same time a low current consumption then the anti-aliasing (AA) filter has to be as simple as possible. The simplest possible filter is a simple 1<sup>st</sup> order RC filter. Any active component will add to the current consumption and add to the noise. A simple first. E.g. A simple RC filter will have the lowest noise and the lowest power consumption. In order achieve sufficient AA- filtering the ratio between the AA filter cut-off and the sampling frequency has to be sufficiently large. As explained in the section on the optimal architecture there are natural limits in how low the AA filter frequency can be made in order to achieve low noise and small die area. This has the consequence that the sampling frequency should be relatively high. The current consumption of the A/D converter will be marginally higher with the very high sampling frequency but all in all the solution with a very simple RC filter as AA filter proves the best overall results

in respect to low noise, small die area and low current consumption. The preferred implementation is a simple RC filter with no buffer or amplifier between the modulator and the filter. As this would only reduce the signal to noise ratio, increase the current consumption and the die area.

5

If a high frequency signal with large amplitude is present then a better solution can be to integrate the anti-aliasing filter into the preamplifier. This solution has higher noise and larger area, but might prove to have better THD (Total Harmonic Distortion) performance.

10

This solution will not be optimum with respect to noise and area but will in case of large high frequency signals (e.g. ultrasonic signals) be advantageous as the amplifier will have very low gain at these frequencies. That is, signals at high frequencies will not be amplified and thus the risk that they overload the amplifier is diminished. This solution provides an ability to suppress high frequency signals. However, the ability to suppress these signals is traded for a larger noise level and a larger chip area (ie cost). The solution is advantageous in that it is very easily incorporated by changing the characteristic of the feedback network slightly at higher frequencies. If a higher order filter characteristic eg of second order is required, a configuration with a combination of an anti-aliasing filter implemented in the preamplifier (thereby providing a band-pass characteristic of the preamplifier) and an anti-aliasing filter coupled between the preamplifier and the D/A converter can be advantageous with respect to chip area.

25

The invention is provide in a **fifth aspect** by using an over-sampled sigma delta converter. Apart from the advantage of using a over sampled AD-Converter in conjunction with a simple RC filter using over sampled A/D converters also has advantage in terms of smaller die area. I.e. For a given noise and current consumption specification the size of the capacitors becomes smaller the larger the over sampling factor. This is under the

30

assumption that the technology (E.g. CMOS) doesn't limits the performance first. E.g. For a 0.5um CMOS the capacitors can be scaled with very small penalties upto a clock frequency of 4-6 MHz. Which for audio purpose AD converters gives a large over sampling factor. For more modern technology this limit are moved even further up.

If the anti-aliasing filter is build into the preamplifier (i.e. the preamplifier, by means of its feed-back circuit, is configured to implement the anti-aliasing filter) then the same advantages apply when using an over-sampled A/D converter or sigma delta modulator. That is, the anti-aliasing filter can be implemented simpler and with smaller area and with lower noise.

The invention is provide in a **sixth aspect** by integrating a voltage regulator on chip the same chip as the amplifier and the A/D-converter.

By implementing the regulator on chip possible savings in other parts of the system are possible. I.e. A possible all digital mobile terminal architecture. Furthermore by adding the voltage regulator on chip the possibility of design a voltage regulator that uses no external components Exists. This is a very effective way of reducing cost as the obviously the cost of an external component has been removed. But also the need for an extra pad for the external component has been removed and thus making the die area smaller. The only way of designing a cost effective on chip regulator without the need of an external component is to use a regulator with a source follower output. Unfortunately this normally has a large drop out voltage. I.e. Larger than the gate source voltage. This can though be overcome by using a switched circuitry to increase the gate voltage level to above the supply voltage. Thus also allowing low voltage operation with a source follower regulator.

30

The invention is provided in a **seventh aspect** by integrating digital signal processing and or digital functionality on the same chip as the amplifier and the A/D-converter. Cost savings can be achieved in many ways, some on component level others on architectural level. E.g. the architecture of a mobile phone. Some parts of the digital signal processing are best done close to the microphone and can thus enable cost savings on the architectural level.

The invention is provided in a **eight aspect** by integrating a voltage pump on the same chip as the amplifier and the A/D-converter. Some microphone types requires a bias voltage in order to function. E.g. Silicon microphones. There are several advantages of integrating this bias voltage on the same chip as the preamp and the A/D converter.

Such as bias voltage is normally higher than the supply voltage. In fact it can be as high as 30V and thus many times higher than the power supply. Such a bias voltage is generated using a voltage pump which typically can consist of a Dickson pump, an oscillator and some kind of reference.

In the case that the pump is integrated together with the A/D, a clock frequency is already present and the oscillator is not needed. Furthermore as the clock for the A/D and for the voltage pump the clock noise from the voltage pump is synchronised with the sampling and is thus a less severe problem.

If the microphone is biased at a DC high voltage then a DC coupling capacitance is needed as then amplifiers in nearly all cases are not able to handle the large DC level without overload. Furthermore by integrating everything on the same chip the total performance can be optimized giving the best possible performance.

The invention is provided in a **ninth aspect** by using a preamplifier with built in offset.

In all the mentioned amplifier configurations it is not shown how the DC bias points are set. Especially in the case of a single ended power supply the setting of the bias points are an important detail. E.g. The outputs of the differential amplifier should ideally have a DC level equal to half of the power supply for the differential preamplifier. I.e. In order to allow the largest possible signal swing at the output. One way is to build in an offset in the preamplifier. In case of a differential preamp it can be build into one of the preamps or both. Another solution is to apply a offset at one of the inputs of the amplifier. In that case a DC coupling is needed to separate the DC on the input from the microphone.

#### Brief description of the drawings

The invention will be described in more detail and with reference to a preferred embodiment, in which:

fig. 13 is a schematic view of a microphone with an integrated circuit and a microphone member.

15

- Fig. 1 shows a digital microphone comprising an electret microphone member, a differential amplifier and an A/D converter. The electret microphone member 115 is biased via a bias resistor 104 that is coupled to a bias voltage Vb. Thereby an electric charge is provided to the membrane or  
20 movable member of the microphone 105, Cmic. A signal provided in response to a sound pressure on the microphone and thus making the membrane move is provided to an amplifier 101. The amplifier 101 is characterised by having a gain characteristic with relative low gain for frequencies below an audible range and a relative high gain for frequencies  
25 in the audible range. Preferably, the gain characteristic descends as a 1<sup>st</sup>, 2<sup>nd</sup>, 3<sup>rd</sup>, 4<sup>th</sup>, or higher order below the audible range. In addition thereto the amplifier is characterised by processing a low frequency microphone signal as a common-mode signal and a high frequency microphone signal as a differential mode signal. Thereby low frequency components are effectively  
30 suppressed.

The output of the amplifier 101 is provided to a sigma-delta A/D converter 103 via an anti-aliasing filter, AAF, 102. The sigma-delta converter provides an over-sampled 1-bit output signal.

- 5 Fig 1a shows a digital microphone comprising a microphone member, a differential amplifier with a band-pass filter and an A/D converter. The electret microphone member 115 is biased via a bias resistor 104 that is coupled to a bias voltage  $V_b$ . Thereby an electric charge is provided to the membrane or movable member of the microphone 105,  $C_{mlc}$ . A signal provided in response to a sound pressure on the microphone and thus making the membrane move is provided to an amplifier 106. The amplifier 106 is characterised by having a gain characteristic with relatively low gain for frequencies below an audible range, a relatively high gain for frequencies in the audible range, and a relatively low gain for frequencies above the audible range. Preferably, the gain characteristic descends as a 1<sup>st</sup>, 2<sup>nd</sup>, 3<sup>rd</sup>, 4<sup>th</sup>, or higher order below and above the audible range. In addition thereto the amplifier is characterised by processing a low frequency microphone signal as a common-mode signal and a high frequency microphone signal as a differential mode signal. Thereby low frequency components are effectively suppressed. Thus, the differential amplifier implements a band-pass filter. The function of the band-pass filter amplifier is to suppress signals at frequencies below the pass-band ie the audible range to avoid overload of the input stage of the differential amplifier and to suppress frequencies above approximately the Nyquist frequency to avoid aliasing problems in subsequent sampling and digitalizing of the signal output from the band-pass filter amplifier. Thereby, a separate anti-aliasing filter can be avoided.

- Fig. 2 shows a differential amplifier with input and output terminals and signals illustrating a low frequency behaviour of the differential amplifier. The signal processing of amplifier 101 at low frequencies is illustrated. The curve 201 illustrates a microphone signal in the time-domain input to the amplifier

( $\phi$ ) and at a low frequency. The curves 202 and 203 illustrates that respective outputs ( $\phi$ ,  $\phi^*$ ) of the amplifier are substantial in phase and thus represent a common-mode differential signal.

- 5 Fig. 3 shows the differential amplifier with input and output terminals and signals illustrating a high frequency behaviour of the differential amplifier. The signal processing of amplifier 101 at high, audio band, frequencies is illustrated. The curve 301 illustrates a microphone signal in the time-domain input to the amplifier ( $\phi$ ) and at a audio frequency. The curves 302 and 303  
10 illustrates that respective outputs ( $\phi$ ,  $\phi^*$ ) of the amplifier are substantial 180 degrees out of phase and thus represent a differential-mode differential signal.

- 15 Fig. 4 shows a portion of a digital microphone comprising an electret microphone member and a differential amplifier in a first configuration.

- 20 Fig 4a shows an embodiment of a feedback network for a preamplifier with a band-pass filter function. The feedback network is shown with general impedances on the left hand side and with specific components on the right hand side.

- The feedback network corresponds to the feedback network shown in fig. 4 with the components 407, 408, 409 designated with general impedances Z. The feedback network comprises a first feedback path a1-b1 for a first signal  
25 path of the two signal paths through the differential amplifier and a second feedback path a2-b2 for a second signal path of the two signal paths through the differential amplifier. The path a1-a2 represents a coupling between the two feedback paths.

- 30 At a specific frequency the impedance of the resistor R1 is equal to that of the capacitor C1. Above this frequency the resistor has the largest

impedance and thus the dominating influence on the circuit. Below this frequency the capacitor is dominating.

5 Fig 4b shows equivalent circuits of the differential amplifier comprising two operational amplifiers/Operational Transconduction Amplifiers and the feedback network for the pass-band i.e. at audio frequencies and the frequencies above the upper cut-off frequency i.e. at the upper stop-band.

10 At a specific frequency the impedance of the resistor R1 is equal to that of the capacitor C1. Above this frequency the resistor has the largest impedance and thus the dominating influence on the circuit. Below this frequency the capacitor is dominating. This is shown in figure 4b where the two equivalent circuits are drawn: one below the upper cut-off frequency off the feedback filter (i.e.  $R1 < \text{abs}(1/sc1)$ ) and one above (i.e.  $1 > \text{abs}(1/sc1)$ ).

15 Normally this is designed so that the upper cut-off frequency is just above the audio band. But in case the preamplifier is connected to an over-sampled A/D converter then it might be much higher.

20 As seen from these two equivalent circuits audio band signals will be amplified where signals with frequencies above the cut-off frequency will be filtered with a  $1/s$  filter function. Furthermore it can be seen that the amplifiers are unity gain coupled for higher frequencies which is greatly beneficial for the distortion performance.

25 Fig. 5 shows a portion of a digital microphone comprising an electret microphone member and a differential amplifier in a second configuration. The electret microphone member is biased via a bias resistor 504 that is coupled to a bias voltage Vb. Thereby an electric charge is provided to the  
30 membrane or movable member of the microphone 505, Cmic. In order to block the DC bias voltage, Vb, from the input of the differential amplifier 510

a capacitor 508 is applied. The differential amplifier 510 is configured as a so-called instrumentation amplifier wherein two operation amplifiers 501 and 502 each are coupled with a feedback path from their respective outputs  $\phi$ ,  $\phi^*$  to their respective inverting input terminal. The inverting inputs of the operation amplifiers are coupled together by means of a capacitor 508. A non-inverting input of the one operational amplifier 501 is coupled to receive the microphone signal via the DC-blocking capacitor 506. A non-inverting input of the other operational amplifier 502 is coupled to receive a feedback signal from the output  $\phi$  of the other operational amplifier via a resistor 512. The non-inverting input is also coupled to ground by means of a capacitor 513.

The feedback path of the operational amplifier 501 comprises a resistor 503 and a capacitor 509 coupled in parallel to constitute a first order filter. Likewise, the feedback path of the operational amplifier 502 comprises a resistor 511 and a capacitor 507 coupled in parallel to constitute a first order filter.

The RC network comprising resistor 512 and capacitor 513 is configured to provide a gradually shifting phase of the signal

The phase shift between the one side, constituted around operational amplifier 501, of the differential amplifier and the other side, constituted around operational amplifier 502 is implemented partly by capacitor 508 and partly by the RC filter 512, 513. Thus, the phase shift is obtained by a phase shifter, capacitor 508, coupled between inputs of the differential amplifier and a phase shifter, capacitor 513 and resistor 512, cross coupled between an output of one side of the differential amplifier and an input of the opposite side of the differential amplifier. Thus, the effective phase shift is obtained by means of two phase shifters. However, one of such two coupled phase shifters may be sufficient to establish the effective phase shift. Likewise,

other configurations of phase shifters can be embodied without departing from the scope of the invention.

Fig. 6 shows a portion of a digital microphone comprising an electret  
5 microphone member and a differential amplifier with a feedback filter. In this illustration a differential amplifier 607 with a first and a second operational amplifier is shown with a filter block 603. The filter block 603 implements feedback paths of the respective operational amplifiers and coupling of the inverting inputs of the respective operational amplifiers 601 and 602.

10

The filter block can implement a filter with two feedback paths of any order eg a 1<sup>st</sup> order, 2<sup>nd</sup> order, 3<sup>rd</sup> order, 4<sup>th</sup> order or any higher order.

Fig. 7 shows a preferred embodiment of a feedback filter. The feedback filter  
15 can implement the filter block 603 of fig. 6.

Fig. 8 shows a switch-capacitor detection of a differential signal to be input to an A/D converter. A switch-capacitor detection of differential signals is known to a person skilled in the art, but is shown to illustrate interconnection of a  
20 differential amplifier with a below audio band cut-off characteristic and a sigma-delta converter. In this illustration an anti-aliasing filter is not shown, but would typically be required to remove spectral components above a sampling frequency of the converter.

25 Fig. 9 shows a first digital microphone. In this aspect of the invention, the digital microphone 901 comprises an integrated circuit 902 with a microphone voltage bias circuit 903, 904; an amplifier 905 with a transfer characteristic which suppresses spectral components below an audio band and provides a substantial flat frequency response for audio frequencies at a nominal gain;  
30 an anti-aliasing filter 906 and a sigma-delta converter 907. The integrated circuit 902 comprises terminals Tc1, Tc2, Tc3, Tc4 for coupling to the

microphone element 908, the bias voltage, a ground reference potential and a supply voltage, respectively. Terminal Tc6 provides a digital signal from the A/D converter and via terminal Tc5 a clock signal is provided to the A/D converter. The supply voltage to the amplifier 905 and the sigma-delta converter can be provided via the terminal Tc6, in which case the terminal Tc4 can be omitted.

In a preferred embodiment the configuration of the band-pass filter amplifier 106 and the A/D converter or sigma-delta converter 103 shown in fig. 1a replaces the configuration of high-pass filter amplifier 905 followed by the anti-aliasing filter 906.

Fig. 10 shows a second digital microphone. In this aspect of the invention, the digital microphone 1001 comprises an integrated circuit 1002 with a DC voltage regulator 1003 which provides a regulated voltage to the amplifier 1009 and the sigma-delta converter 1011. The microphone bias voltage is provided by an on-chip voltage up-converter 1004 which receives an off-chip oscillating signal with a voltage amplitude; in response thereto the up-converter provides an output oscillating signal with a larger voltage amplitude. This output signal is low pass filtered by low pass filter 1005 and provided via a series resistor 1006 to the microphone element 1008. A capacitor 1007 blocks the DC bias voltage from the input of the amplifier 1009 with the transfer function mentioned above. Output of the amplifier 1009 is provided to an anti-aliasing filter 1010 before being input to a sigma-delta converter 1011.

The voltage up-converter or voltage pump, UPC, 1004 can be in the form of a so-called Dickson-converter. The voltage pump is operated by an oscillator which preferably provides a square-wave oscillator signal to the voltage pump. Other signals, eg sine waves or filtered square waves, with lower

contents of harmonics may be used to obtain lower noise. As an alternative, the oscillator can be embedded on the chip 1002.

5 It is shown that the up-converter and the sigma delta converter shares the same oscillator/clock signal as provided via terminal Tc4. It should be noted that the signal may be divided to obtain different oscillating/clock signal frequencies to the UPC and sigma-delta converter.

10 In a preferred embodiment the configuration of the band-pass filter amplifier 106 and the A/D converter or sigma-delta converter 103 shown in fig. 1a replaces the configuration of high-pass filter amplifier 1009 followed by the anti-aliasing filter 1010.

15 Fig. 11 is a block diagram of a digital microphone.

In a preferred embodiment the configuration of the band-pass filter amplifier 106 and the A/D converter or sigma-delta converter 103 shown in fig. 1a replaces the configuration of high-pass filter amplifier 1101 followed by the anti-aliasing filter 1102.

20

Fig. 12 is another block diagram of a digital microphone. Here, a buffer or buffer amplifier is inserted before the sigma-delta converter.

25 In a preferred embodiment the configuration of the band-pass filter amplifier 106 and the A/D converter or sigma-delta converter 103 shown in fig. 1a replaces the configuration of high-pass filter amplifier 1201 followed by the anti-aliasing filter 1202.

30 Fig. 13 is a schematic view of a microphone with an integrated circuit and a microphone member. The microphone is shown as a cartridge with a

microphone member, comprising the microphone membrane and an integrated circuit.

5 Generally, it should be noted that the amplifier of fig. 2, 3, 4, 5 and 6 can be applied in an analogue microphone where a pre-amplified microphone signal is provided as an analogue signal. The analogue signal can be provided as a single ended signal or a differential signal depending on the configuration of the amplifier.

10 Embodiments with a single-ended configuration

A complete single ended solution is implemented as described in the following. First a single ended preamplifier with a high pass filter function. Then followed by a single ended AA filter. And lastly a single ended modulator/A/D converter. By a single ended A/D converter or modulator is  
15 meant a modulator or A/D converter which processes the signal single ended. In nearly all cases the modulator or A/D converter will have two inputs. E.g. a switched capacitor modulator or A/D converter will have an input capacitor which is switched from one node to another going from the high phase to the low phase of the clock. A switched capacitor circuit works  
20 by measuring charging and discharging of capacitors. So the input capacitor will have to be switched between two nodes. I.e. effectively the modulator will always have two inputs. As a single ended AA filter is used which only has one output then the other input has to be connected to a reference voltage. This should preferably be equal to the DC level of the output of the AA  
25 filter. This reference voltage will always add noise but no signal. Compared to a differential solution which also adds signal then signal to noise ration will thus be lower for the single ended version. It should be noted that the A/D converter can be implemented using other techniques than switched capacitor without departing from the scope of the invention.

30

Effectively it means that an implementation using a fully differential preamplifier and AA filter will have better performance than a fully single ended version. The modulator can be both single ended and differential. A single ended version of the modulator or the A/D converter will though typically have a small die area.

#### Cut-off frequencies

The transfer function of the differential amplifier from single ended input to differential output will as explained, at low frequencies be a common mode signal. I.e. the transfer function will be zero and for higher frequencies it will be a differential signal. Looking at the transfer function to differential output it will typically look as a 1<sup>st</sup> order high pass filter with a cut-off frequency around 1-200Hz typically at 10Hz.

The transfer function from the input to each of the outputs looking on them as single ended outputs will typically also be a 1<sup>st</sup> order high pass filter. Normally one would want to position this below the cut-off of the differential transfer function. As this gives lower noise. This would normally, because of low frequency signals, overload subsequent stages. E.g. AA filter + Modulator. But as the following blocks can be designed to have a large common mode input range and are only detecting the differential signal it is possible to design a preamplifier which both suppresses the low frequency signals and still have good low noise performance.

#### Microphones elements

In this invention a grounded microphone element has been shown as this is most common. But floating microphone elements also exists and here the advantages of the differential preamplifier becomes even more pronounced.

In preferred embodiments, the microphone element and the integrated circuit is implemented on a single chip.

The above features may be applied in embodiments of a preamplifier configuration that comprises a gain stage with a feedback filter, where the configuration has a relatively low gain response for frequencies below an audio band and has a relatively high and substantially flat gain response in the audio band. The audio band can be defined to be any band within the typical definition of an audio band. A typical definition can be 20Hz to 20KHz. Exemplary lower cut-off frequencies for an audio band can be: 20 Hz, 50Hz, 80 Hz, 100Hz, 150 Hz, 200Hz, 250hz. Exemplary upper cut-off frequencies the an audio band could be 3KHz, 5KHz, 8KHz, 10KHz, 18KHz, 20KHz. By substantial flat is meant gain response variations within approximately +/- 1dB; +/-3dB; +/-4dB; +/-6dB. However, other additional values of variation can be used to define the term 'substantial flat'. In this case the bands are defined for audio use but the same arguments can be used for other frequency bands. E.g. Ultrasound frequencies in the range from 100kHz to 20MHz.

CLAIMS

1. An integrated circuit configured to microphone signals processing; the integrated circuit comprising an amplifier with a feedback path comprising a low pass filter; the amplifier configured to provide an output signal to a sigma delta modulator via an anti-aliasing filter.  
5
2. An integrated circuit according to claim 1, wherein the amplifier has a relative low gain at frequencies below audio band frequencies and a relative high gain at frequencies in the audio band.  
10
3. An integrated circuit according to claim 1, wherein the amplifier is a differential amplifier which is configured to convert an input signal into a common mode signal for low frequencies and into a differential signal for audio frequencies.  
15
4. An integrated circuit according to claim 1, wherein a differential amplifier is configured as an instrumentation type amplifier with two inputs and a first and a second output, wherein the first and second input is arranged to receive a microphone signal, but wherein the inputs are coupled to receive the microphone signals substantially in phase at relatively low frequencies and substantially out of phase at relatively high frequencies.  
20
5. An integrated circuit according to claim 1, wherein a differential amplifier is configured to provide frequencies below an audio band as common mode signals and audio band signals as differential mode signals.  
25
6. An integrated circuit according to claim 3, wherein a phase shifter is coupled between inputs of the differential amplifier.  
30

7. An integrated circuit according to claim 1, wherein a phase shifter is cross coupled between an output of one side of the differential amplifier and an input of the opposite side of the differential amplifier.
- 5 8. An integrated circuit according to claim 3, wherein a phase shifter is coupled between a signal node, substantially in phase with an input signal to the amplifier, and an input of an opposite side of the differential amplifier
9. An integrated circuit according to claim 1, wherein the amplifier is
- 10 configured as a preamplifier.
10. A microphone configured to provide a digital signal and comprising an integrated circuit as set forth in any of the preceding claims 1 to 9.
